(Received 12 May 2011)

Large scale mean flows often emerge in turbulent fluids. In this work we formulate a stability theory, the stochastic structural stability theory (SSST), for the emergence of jets under external random excitation. We analytically investigate the structural stability of a two dimensional homogeneous fluid enclosed in a channel and subjected to homogeneous random forcing. We show that two generic competing mechanisms control the instability that gives rise to the emergence of an infinitesimal jet: advection of the eddy vorticity by the mean flow that is shown to be jet forming and advection of the vorticity gradient of the jet by the eddies that is shown to hinder the formation of the mean flow. We show that stochastic forcing with small streamwise coherence and an amplitude larger than a certain threshold leads to the emergence of jets in the channel through a bifurcation of the non-linear SSST system.

1. Introduction

Large scale jets that are maintained by the eddy field are commonly observed in turbulent flows. Prominent geophysical examples are the large streamwise flows that are observed in the upper atmosphere of the gaseous planets and the Earth’s polar front jet. Examples from laboratory experiments include the strong jets in the vicinity of the boundaries of channels in cases of turbulent convection (Krishnamurti & Howard 1981), the driving by convection of banded jets in rotating tank experiments (Read et al. 2004) and the emergence of streamwise flows in fusion plasma devices (Fujisawa et al. 2008). Analysis of the velocity fields and theoretical arguments have demonstrated that these jets are maintained by the Reynolds stresses of the eddy field with which they coexist (Jeffreys 1926; Kuo 1951; Starr 1968; Ingersoll 1990; Vasavada & Showman 2005; Read et al. 2007; Diamond et al. 2005).

These large scale flows are complex, time-dependent solutions of the Navier-Stokes equations and even though they exhibit a great degree of stationarity, they are not stationary points of the equations. Consequently, in order to treat the stability of these turbulent flows, the classical stability theory originating from the pioneering work of Rayleigh (1880) has to be extended. The reason is that it only treats stationary mean flows that are maintained by an external thermal or pressure gradient. Formulation of such an extended theory requires two main components. The first component is a definition of what is meant by an equilibrium in these turbulent fluids. The second component is
a method to obtain the structure of the turbulence and the associated Reynolds stresses, as well as model the eddy influence on the mean flow.

A framework that provides a method for formulating and calculating the stability of mean flows in turbulence is Stochastic Structural Stability Theory (hereafter SSST) developed by Farrell & Ioannou (2003). In the context of SSST, equilibria are not defined as fixed points of the field equations alone (as in Charney & DeVore (1979); Pierrehumbert & Malguzzi (1984); Legras & Ghil (1985); Marshall & Molteni (1993); Dijkstra & Katsman (1997); Simonnet et al. (2005) for geophysical flows, or as in Waleffe (2003); Faist & Eckhardt (2003); Wedin & Kerswell (2004); Duguet et al. (2009) for laboratory flows) nor as maximum entropy structures (Robert & Sommeria 1991; Bouchet & Sommeria 2002). The equilibria are instead fixed points of a set of autonomous statistical dynamical equations for the average eddy-mean flow interaction and the associated evolution of the average eddy field. The average can be defined in various ways depending on the physical situation. Most comprehensively, a time average is considered over a time scale intermediate between the fast time scale of the eddies and the slow time scale of the evolution of the large scale flow. In this work, we will consider channel flows and will employ averages in the streamwise direction parallel to the channel boundaries.

Regarding the generation of mean flows in turbulent fluids, there are three main approaches: the cascade theory of Rhines (Rhines 1975), modulational instability (Lorenz 1974; Gill 1974) and formation of mean flows from interaction of eddies with the large scale mean shear. The first approach starts with the pioneering work of Rhines (Rhines 1975) on turbulence on a \( \beta \) plane. Rhines (1975) proposed that non-linear eddy-eddy interactions lead to an inverse energy cascade that is ‘arrested’ by weakly interacting Rossby waves. Because \( \beta \) has a stronger effect on eddies that are elongated along the cross-stream axis, the ‘arrest’ is anisotropic in wavenumber space and allows the upscale energy transfer to a streamwise flow (Vallis & Maltrud 1993; Nazarenko & Quinn 2009). However, observations of quasi-geostrophic turbulence in the atmospheric midlatitude jet (Shepherd 1987) and numerical analysis of simulations (Huang & Robinson 1998; Nozawa & Yoden 1997; Huang et al. 2001; Berloff et al. 2009a,b) showed that the energy transfer between the eddies and the streamwise jet is spectrally nonlocal. Huang & Robinson (1998) found that even though the large scale eddies at the Rhines scale interact with the streamwise jet on short timescales, they contribute little to the net maintenance of the mean flow. The reason is that in the long term this interaction is statistically incoherent and averages to nearly zero in the time mean. Huang & Robinson (1998) demonstrated that the mean flows are instead maintained from the non local interaction between the mean flow and eddies with scales smaller than the Rhines scale.

One such non-local theory for the generation of mean flows is modulational instability in which a primary meridional Rossby wave of finite amplitude leads transfers its energy directly to the mean flow (Lorenz 1974; Gill 1974; Connaughton et al. 2010). Recently, Berloff et al. (2009a) have shown in numerical simulations of a baroclinic two-layer model, that Rossby waves emerging from baroclinic instability of the mean flow become secondarily unstable when they reach a finite amplitude. They then feed energy directly to the streamwise flow along the lines of modulational instability.

The findings of Huang & Robinson (1998) are the basis of the third approach, pursued in SSST. SSST proposes an eddy-mean flow interaction mechanism for mean flow emergence and persistence. The eddy mean flow interaction, can be well approximated using a Stochastic Turbulence Model (STM). In the STM, the eddies draw most of their energy from the mean flow while the eddy excitation is represented as stochastic forcing (Farrell & Ioannou 1993a,b,c; DelSole & Farrell 1996; Newman et al. 1997; DelSole 2004). The stochastic forcing may represent excitation by external processes such as convection
Structural stability theory of two dimensional fluid flow under stochastic forcing

(as in the case of the Jovian jets or in the rotating tank experiments of Read et al. (2004)) or it may additionally represent a parametrization of the nonlinear eddy-eddy interactions. As a result, the STM is a Langevin model of turbulence derived from the linearized Navier-Stokes equations in the spirit of rapid distortion theory (Hunt & Corruthers 1990). The advantage of the STM is that it provides a closure that determines a Gaussian approximation to the eddy statistics for any given mean flow. Its accuracy was extensively verified with fully nonlinear numerical studies of the eddy statistics in quasigeostrophic turbulence (DelSole & Farrell 1996; DelSole 1996; Whitaker & Sardeshmukh 1998; Zhang & Held 1999; DelSole 2004) and has also been used to explain the turbulent structure in laboratory channel flows (Farrell & Ioannou 1993c, 1998; Bamieh & Dahleh 2001; Jovanovic & Bamieh 2005; Hwang & Cossu 2010). Finally, this approximation has been shown to accurately predict the coherent flow structures for both the resolved and the largest sub-grid scales in three dimensional turbulence under even homogeneous and isotropic conditions (Laval et al. 2003). The amplitude of the stochastic forcing will be taken as constant in this work. While for extrinsic sources of turbulence this is probably a good assumption, it is a crude assumption when the eddy excitation represents the nonlinear scattering to other scales, because its amplitude depends then on the very presence of the eddies. Progress on this problem has been made (DelSole 2001; Farrell & Ioannou 2009c) and while an attractive avenue for future study, such a closure is not necessary for understanding the basic dynamics underlying the structural instability of the resulting equilibria.

In the context of SSST, the average eddy statistics provided by the STM are combined with the evolution equation for the mean flow to form an autonomous non linear system governing the joint evolution of the mean flow and the associated eddy statistics. The fixed points of this system represent steady mean flows in equilibrium with the mean eddy forcing and dissipation. The instability of these equilibria which brings about structural reconfiguration of the mean flow and the eddy statistics can then be studied. Using these methods, the structural instability of the joint eddy-mean flow equilibria have already been studied in barotropic and baroclinic rotating atmospheres (Farrell & Ioannou 2007, 2008, 2009a; Bernstein & Farrell 2010), and in the case of poloidal flow formation in tokamaks by drift wave turbulence (Farrell & Ioannou 2009b).

In this work we investigate within the framework of SSST the role of the eddy mean flow feedbacks in the instability of the eddy-mean flow system equilibria giving rise to a mean flow. That is, we will focus on the mechanisms underlying the organization of the eddies by mean flow variations to produce Reynolds stresses that amplify these variations and eventually lead to an emerging jet. This paper is organized as follows. In § 2 we describe the evolution equations for the eddy-mean flow coupled system. In § 3 we calculate the eigenvalues of the linear operator governing the stability of the eddy-mean flow equilibria. In § 4 we elaborate on the role of the eddy-mean flow feedbacks and discuss the characteristics of the emerging jet in § 5. Sensitivity of the obtained results to changes in the eddy forcing and dissipation, is examined in § 6. We finally end with a brief discussion of the obtained results in § 7 and our conclusions in § 8.

2. Evolution equations for a barotropic flow

Consider a forced incompressible, planar flow confined in a channel \((-\infty < x < \infty\) and \(0 \leq y \leq 2\pi\)) on which we impose periodic boundary conditions at \(y = 0\) and \(y = 2\pi\). A streamfunction \(\psi\) can be defined such that: \([u, v] = [-\psi_y, \psi_x]\), where \(u, v\) are the streamwise, \(x\), and cross-stream, \(y\), components of velocity. The streamfunction evolves
as:

$$\partial_t \Delta \psi + J(\psi, \Delta \psi) = -r \Delta \psi + \nu \Delta^2 \psi + F_{ext},$$

(2.1)

where $\Delta = \partial^2_{xx} + \partial^2_{yy}$ is the Laplacian, $J(A, B) = A_x B_y - A_y B_x$ is the Jacobian operator, $r, \nu$ are the coefficients of linear and diffusive dissipation and $F_{ext}$ is the external forcing. The forcing is required in two dimensional studies of turbulent flows to sustain a statistical steady state. It represents either the actual excitation (for example stirring by overturning convective systems in giant gas planets) or parameterizes missing three dimensional processes (such as three dimensional instabilities) cascading energy from three dimensional (baroclinic) to planar (barotropic) flows. We decompose the streamfunction into a streamwise mean component (indicated with upper case) and an eddy component (indicated with primed quantities):

$$\psi(x, y, t) = \Psi(y, t) + \psi'(x, y, t),$$

and assume a vanishing external excitation for the mean flow. Under this decomposition and taking a streamwise mean (denoted by an overbar) of (2.1) yields the streamwise averaged equation for the $x$ component of the mean velocity $U = -\Psi_y$:

$$\partial_t U = -\partial_y \psi' - rU + \nu U_{yy}.$$  

(2.2)

We then subtract (2.2) from (2.1) to obtain the evolution equation for the eddies:

$$(\partial_t + U \partial_x) \Delta \psi' - \psi_x' U_{yy} = -r \Delta \psi' + \nu \Delta^2 \psi' + (F_{ext} + F_e),$$

where $F_e = J(\psi', \Delta \psi') - J(\psi', \Delta \psi')$, is the forcing term from the eddy-eddy interactions. Following previous studies of stochastic turbulence modeling (Farrell & Ioannou 1993a, b, 1994, 1995, 1996, 1998; DelSole 1996, 1999, 2001, 2004; DelSole & Farrell 1995, 1996), the eddy forcing term $F_{ext} + F_e$ is represented as a stochastic process. Under this assumption and taking harmonic perturbations of the form $\psi'(x, y, t) = \psi(y, t) e^{ikx}$, the Laplacian becomes $\Delta = D^2 - k^2$, where $D^2 = \partial^2 / \partial y^2$, and the $k$ Fourier component of vorticity $\omega = \nabla^2 \psi$ obeys the stochastic equation:

$$\frac{d}{dt} \omega + ikU_{yy} \omega = \nu D^2 \omega + F \xi(t).$$  

(2.3)

$F, \xi(t)$ are the spatial and temporal structure of the stochastic forcing respectively, and $D^{-1}$ the inverse Laplacian. We will consider an eddy field concentrated at a single wavenumber $k$. We will show in the sequel that we loose no generality by assuming a monochromatic eddy field.

We discretize the differential operators with finite differences. The reason is that although a continuous version of the eddy-mean flow system can be derived, the matrix form of the equations allows the use of matrix calculus. This will be necessary for obtaining the properties of the dynamics of the covariance of the eddy field and will facilitate analytic progress. The operators then, become finite dimensional matrix approximations of the continuous operators and the variables $\omega, U$ become column vectors with elements the values of the variables at the grid points. In matrix notation, (2.3) takes the form:

$$\frac{d\omega}{dt} = A(U) \omega + F \xi(t),$$  

(2.4)

where the spatial structure of the forcing is given by the columns of the matrix $F$ and $\xi$ is a vector giving the time variation of the forcing. $A$ is the matrix form of the linear
dynamics about the mean flow \( \mathbf{U} \) given by:

\[
\mathbf{A}(\mathbf{U}) = -i k \text{diag}(\mathbf{U}) - i k \text{diag}(-\mathbf{D}^2 \mathbf{U}) \Delta^{-1} - r I + \nu \Delta,
\]

where \( I \) is the identity matrix and diag(\( \bullet \)) denotes the diagonal matrix with diagonal elements the vector (\( \bullet \)). The linear dynamics comprise of advection of perturbation vorticity by the mean flow, advection of the mean vorticity gradient \(-\mathbf{D}^2 \mathbf{U}\) by the perturbations and dissipation.

Similarly, (2.2) is written as:

\[
\frac{d \mathbf{U}}{d t} = \mathbf{R} - r \mathbf{U} + \nu \mathbf{D}^2 \mathbf{U}, \tag{2.5}
\]

where

\[
\mathbf{R} = -\partial_y \mathbf{u}' \mathbf{v}' = -\frac{k}{2} \text{vecd}[\text{Im}(\Delta^{-1} \mathbf{\omega} \mathbf{\omega}^\dagger)],
\]

is the Reynolds stress divergence expressed in terms of the streamwise mean enstrophy covariance matrix of the eddy field, \( \mathbf{\omega} \mathbf{\omega}^\dagger \), \( \dagger \) denotes the Hermitian transpose and vecd denotes the operation of extracting the diagonal elements of a matrix.

The random vector process \( \mathbf{\xi} \) has statistically independent elements and is a Gaussian white noise in time with zero mean and unit variance so that:

\[
\langle \mathbf{\xi} \rangle = 0, \quad \langle \mathbf{\xi} \mathbf{\xi}^\dagger \rangle = I \delta(t - s),
\]

where the angle brackets denote an ensemble average over realizations of the forcing. The spatial localization of the excitation is dictated by the matrix \( \mathbf{F} \) which is chosen to have elements

\[
F_{ij} = e^{-\frac{(y_i - y_j)^2}{\delta^2}}.
\]

This specification leads to a statistically homogeneous excitation of the channel with forcing that is coherent over a distance \( \delta \). Finally, the forcing is normalized so that the variance level is a fraction \( \epsilon \) of the energy of a constant mean flow with unit velocity. This normalization stems from the fact that typically the eddy variance is a fraction of the mean flow energy.

The system of (2.4), (2.5) describes the dynamics of a single realization of the stochastically excited wave field interacting with the mean flow. Assuming a large number of independent realizations of the forcing and taking an ensemble average of the excited wave fields, we obtain a deterministic equation governing the evolution of the ensemble average enstrophy covariance matrix \( \mathbf{C} = \langle \mathbf{\omega} \mathbf{\omega}^\dagger \rangle \):

\[
\frac{d \mathbf{C}}{d t} = \mathbf{A}(\mathbf{U}) \mathbf{C} + \mathbf{C} \mathbf{A}^\dagger(\mathbf{U}) + \epsilon \mathbf{Q}, \tag{2.6}
\]

where \( \mathbf{Q} = \mathbf{F} \mathbf{F}^\dagger \) (Farrell & Ioannou 2003). Under an ergodic assumption, the ensemble average of the eddy Reynolds stress is equal to the streamwise average Reynolds stress, that is \( \mathbf{\overline{u}'v}' = \langle \mathbf{u}' \mathbf{v}' \rangle \). The mean flow therefore evolves as:

\[
\frac{d \mathbf{U}}{d t} = \mathbf{R}(\mathbf{C}) - r \mathbf{U} + \nu \mathbf{D}^2 \mathbf{U}, \tag{2.7}
\]

where

\[
\mathbf{R}(\mathbf{C}) = -\frac{k}{2} \text{vecd}[\text{Im}(\Delta^{-1} \mathbf{C})],
\]

is the average Reynolds stress divergence due to the eddy field at wavenumber \( k \). Equations (2.6), (2.7) form a deterministic, autonomous, globally stable nonlinear system for the evolution of the mean flow under the influence of its consistent field of eddies at
wavenumber $k$. The attractor of this system may be a fixed point, a limit cycle, or a chaotic attractor. Examples of each of these behaviors has been found in the SSST description of geophysical and plasma turbulence (Farrell & Ioannou 2003, 2008, 2009b).

The fixed points $U^E$ and $C^E$, if they exist, satisfy simultaneously:

$$A(U^E)C^E + C^E A(U^E) = -\epsilon Q,$$

$$R(C^E) = -rU^E + \nu D^2 U^E,$$

and these define statistical equilibria in the presence of an eddy field with covariance $C^E$.

The stability of the eddy-mean flow equilibria $U^E$ and $C^E$ can then be determined by considering the evolution of small perturbations $\delta U$, $\delta C^R$, and imaginary part, $\delta C^I$, of the perturbation covariance. The resulting stability equations for the evolution of $\delta U$, $\delta C^R$ and $\delta C^I$ can be written in the compact form:

$$\frac{d}{dt} \begin{pmatrix} \text{vec}(\delta C^R) \\ \text{vec}(\delta C^I) \\ \delta U \end{pmatrix} = L \begin{pmatrix} \text{vec}(\delta C^R) \\ \text{vec}(\delta C^I) \\ \delta U \end{pmatrix},$$

where $\text{vec}$ is the vector representation of a matrix obtained by stacking sequentially the columns of a matrix on top of each other. As a result, $\text{vec}(\delta C^R)$ and $\text{vec}(\delta C^I)$ become $N^2 \times 1$ vectors for $N$ discretization points in the channel and $L$ is a $(2N^2+N) \times (2N^2+N)$ matrix. The structural stability operator $L$ determines the stability of the eddy-mean flow equilibria.

It is worth noting that perturbation stability, determined by eigenanalysis of the operator $A^E = A(U^E)$, does not necessarily imply structural stability, determined by eigenanalysis of the operator $L$. If a mean flow is perturbation unstable, it is also structurally unstable. However, the converse is not true. In fact, it will be shown that the state of no mean flow, while perturbation stable in a dissipative fluid, is structurally unstable under sufficient forcing. The reason is that the nonzero eddy fluxes that are maintained by the forcing may induce mean flow changes that will in turn lead to increased fluxes resulting in a positive feedback and in instability of $L$. It is this eddy-mean flow instability leading to the emergence of mean flows in a turbulent fluid that is addressed in this study. In the following sections, the diffusive eddy dissipation will initially be ignored and its effect on the jet forming instability will be considered in § 7.

3. The structural stability operator for a statistical equilibrium with no mean flow

Because an eddy field in a constant flow cannot produce a Reynolds stress divergence $R$, the state with no mean flow ($U^E = 0$) and an eddy field with covariance

$$C^E = \frac{\epsilon Q}{2r},$$

is a fixed point of the system (2.6)-(2.7). The goal is to determine the structural stability of this statistical equilibrium state that has no mean flow associated with it. The structural stability operator $L$ of (2.8) takes in this case the form (see Appendix A for the derivation):

$$L = \begin{pmatrix} -2r I_{N^2} & 0 & 0 \\ 0 & -2r I_{N^2} & L^{UI} \\ 0 & L^{IU} & -r I \end{pmatrix},$$

where $I_{N^2}$ is the $N^2 \times N^2$ identity matrix. The operator $L^{UI}$ determines the change in the Reynolds stress divergence, $R$, due to a change in the eddy statistics $\delta C$ and is given
by:

\[ L^{UI} = \frac{\partial R}{\partial \delta C} = -\frac{k}{2} J(I \otimes \Delta^{-1}), \] (3.3)

where \( \otimes \) denotes the Kronecker product defined in Appendix B and \( J \) is the \( N \times N^2 \) selection matrix given in Appendix A that extracts the diagonal elements of a matrix (see equations (A 7) and (A 9)). On the other hand, the operator \( L^{IU} \) determines the change in the eddy statistics \( \delta C \) due to the change in the mean flow \( \delta U \) and is given by:

\[ L^{IU} = -\frac{\epsilon k}{2r} \left\{ Q \ast I - I \ast Q - \left[ (Q\Delta^{-1}) \ast I - I \ast (Q\Delta^{-1}) \right] D^2 \right\}, \]

where \( \ast \) denotes the Khatri-Rao product defined in Appendix B.

From (3.2) we immediately see that the block-diagonal matrix \( L \) has \( N^2 \) eigenvalues \( \lambda = -2r \) (from the upper block), with corresponding eigenvectors \([\delta C^R, \delta C^I, \delta U] = [I, 0, 0] \)), representing decay of the perturbation covariance. In addition, because \( L^{UI} \) is an \( N \times N^2 \) matrix, the \( N^2 - N \) vectors \([\delta C^R, \delta C^I, \delta U] = [0, E, 0] \), with \( E \) one of the \( N^2 - N \) basis vectors of the nullspace of \( L^{UI} \) (c.f Appendix A), are eigenvectors of \( L \) with eigenvalue \( \lambda = -2r \). As a result, \( L \) has a total of \( 2N^2 - N \) decaying eigenmodes with eigenvalue \( -2r \) and \( \delta U = 0 \) that do not modify the mean flow. The remaining \( 2N \) eigenvalues can be calculated by taking the time derivative of the equation corresponding to the third row in (2.8) and using the equation corresponding to the second row in (2.8) to obtain:

\[ \frac{d^2 \delta U}{dt^2} + 3r \frac{d\delta U}{dt} + (2r^2 I - L^{UI} L^{IU}) \delta U = 0. \] (3.4)

Looking for modal solutions of the form \( \delta U = e^{s_n t} \delta U_n \) in (3.8) we obtain:

\[ \lambda_n = -\frac{3r}{2} \pm \frac{1}{2} \sqrt{r^2 + 4s_n}, \quad n = 1, \ldots, N, \] (3.5)

where \( s_n \) are the \( N \) eigenvalues of the \( N \times N \) matrix \( S = L^{UI} L^{IU} \). From (3.5) we obtain that the zero mean flow equilibrium becomes unstable and mean flows emerge only if the eigenvalues of \( S \) are positive.

Matrix \( S \) determines the sensitivity of the Reynolds stress divergence to small changes in the mean flow in the quasi-static limit. That is, if we assume that the mean flow evolves slowly enough that it remains in equilibrium with the eddy covariance and satisfies at all times

\[ A(U) \mathcal{C} + CA^I(U) = -\epsilon Q, \] (3.6)

then the covariance perturbation becomes a function of the instantaneous mean flow perturbation. This \( \delta C(\delta U) \) is found by solving (3.6) linearized around the equilibrium values or equivalently by solving \( d\delta C/dt = 0 \). As a result, the change in the imaginary part of the covariance is in the notation of (3.2) given by:

\[ \text{vec} (\delta C^I) = (1/2r) L^{UI} \delta U. \] (3.7)

In that approximation, the change in the Reynolds stress divergence induced by a change in \( \delta U \) is obtained by combining (3.3) with (3.7):

\[ \delta R = \frac{\partial R}{\partial \delta C^I} \text{vec} (\delta C^I) = L^{UI} L^{IU} \delta U = \frac{1}{2r} S \delta U. \]

It is instructive to consider the predictions of mixing-length theory for the sensitivity operator \( S \). According to the mixing-length hypothesis, the eddy momentum flux is assumed proportional to the gradient of mean velocity \( \overline{w'v'} = -\mu (dU/dy) \), with \( \mu > 0 \),
yielding a Reynolds stress divergence proportional to the curvature of the flow:
\[ R = - \partial_y u v' = \mu \frac{d^2 U}{dy^2}. \]
So \( S \) is the second derivative operator: \( S = \mu D^2 \) which has negative eigenvalues and acts as diffusion in the cross-stream direction. As a result, according to mixing length theory a state of zero mean flow in the presence of an eddy field would always be structurally stable and no mean flows could emerge. In the next section we show that, quite generally, \( S \) is the sum of two commuting operators. The first is a diffusion operator with negative coefficient of viscosity (anti-diffusion) and the other a diffusion or hyper-diffusion operator. We also show that the zero mean flow can be rendered structurally unstable in the presence of homogeneously forced eddies.

It is also worth addressing the case of an eddy field that comprises of a band of wavenumbers \( k \). It can be readily shown that in this case, the eigenvalues of the structural stability operator are obtained by solving:
\[ \frac{d^2 \delta U}{dt^2} + 3r \frac{d\delta U}{dt} + \left( 2r^2 l - \sum_k S_k \right) \delta U = 0, \quad (3.8) \]
where \( S_k = L_k^U L_k^U \) is the sensitivity operator at each streamwise wavenumber \( k \). Since \( S_k \) can be shown to commute, the eigenvalues of the structural stability operator are given in this case by:
\[ \lambda_n = -\frac{3r}{2} \pm \frac{1}{2} \sqrt{r^2 + 4 \sum_k s_n(k)}, \quad n = 1, \ldots, N, \quad (3.9) \]
where \( s_n(k) \) are the eigenvalues of \( S_k \). Note that this result pertains to the simplified case considered here. The same analysis on a \( \beta \) plane, or including diffusive dissipation (as treated in Appendix D), yields similar results only in the asymptotic limits of \( \beta \ll 1 \) and \( \nu \ll 1 \).

4. Eigenvalues of the Reynolds stress sensitivity operator for a statistical equilibrium with no mean flow

In Appendix A, it is shown that the sensitivity operator is the sum of two commuting operators:
\[ S = \frac{ck^2}{4r} \begin{cases} \frac{[Q \circ \Delta^{-1} - I \circ (\Delta^{-1} Q)] - [\Delta^{-1} \circ (Q\Delta^{-1}) - I \circ (\Delta^{-1} Q\Delta^{-1})]}{S^{\text{ad}}} \end{cases} \quad D^2 \],
where \( S^{\text{ad}} \) determines the sensitivity of the Reynolds stress divergence to changes in the mean velocity advection. The first operator, \( S^{\text{ad}} \), determines the sensitivity of the Reynolds stress divergence to changes in the mean vorticity gradient. The commutation of these two operators as well as many of the properties that allow analytical progress, derive from the fact that all the matrices in (4.1) are real symmetric and circulant. This matrix property is defined in Appendix C and reflects the periodicity and the translational invariance in the cross-stream direction. Because the Hadamard product of symmetric and circulant matrices is also symmetric and circulant, both \( S^{\text{ad}} \) and \( S^{\text{vq}} \) are real symmetric and
Structural stability theory of two dimensional fluid flow under stochastic forcing

circulant, have real eigenvalues, $s_n^{ad}$ and $s_n^{vg}$, and eigenfunctions, the harmonic basis functions:

$$\delta U_n = \sin (n y),$$

where $y$ is the column vector with $i$-th element the collocation point $y_i$, $i = 1, 2, ..., N$. The eigenvalues of $S$ depend on the wavenumber $n$ of the mean flow perturbation and are given by:

$$s_n = \frac{ek^2}{4r} (s_n^{ad} - s_n^{vg}). \quad (4.2)$$

Both $s_n^{ad}$ and $s_n^{vg}$ are positive if the stochastic forcing is correlated (refer to Appendix C for a proof in the case of homogeneous, Gaussian correlated stochastic forcing). Consequently, advection of the eddy vorticity by the perturbed flow is destabilizing, while advection of the perturbed mean vorticity gradient by the eddies has a stabilizing tendency.

The eigenvalues $s_n^{ad}$ and $s_n^{vg}$ were numerically calculated for $N = 401$ grid points for which the obtained results are resolved. Numerical convergence to the continuous system was verified by doubling the resolution. The computed eigenvalues are shown in figure 1 (dots) as a function of the wavenumber $n$ of the mean flow for two values of the streamwise wavenumber of the eddy field $k$. Useful asymptotic expressions for the eigenvalues are obtained in the continuous limit ($N \to \infty$). If we define the scale of the eddy field as $l_e = \min(1/k, \delta)$, it is shown in Appendix C that for a mean flow perturbation with a small scale compared to the eddy scale ($nl_e \gg 1$):

$$s_n^{ad} \simeq 2, \quad s_n^{vg} \simeq c_1 (k \delta) \frac{n^2}{k^2}, \quad (4.3)$$

where $c_1(k\delta)$ is given by (C26). This implies that high mean flow wavenumbers have $s_n < 0$ and hence from (3.5) are structurally stable. In the more physically relevant regime, in which the scale of the mean flow perturbation is larger than the eddy scale ($nl_e \ll 1$), it is shown in Appendix C that:

$$s_n^{ad} \simeq \left\{ \begin{array}{ll} \delta^2 n^2, & \text{for } kl_e \ll 1 \cr c_2(k, \delta) n^2, & \text{for } kl_e \gg 1 \end{array} \right., \quad s_n^{vg} \simeq \left\{ \begin{array}{ll} 2n^2/k^2, & \text{for } kl_e \ll 1 \cr c_3(k\delta)n^4/k^4, & \text{for } kl_e \gg 1 \end{array} \right., \quad (4.4)$$

where $l_e = 2\pi$ is the width of the channel and the constants $c_2$ and $c_3$ given in (C17) and (C18) respectively depend only on $k$ and on the scale $\delta$ of the forcing. The analytic results of (4.3)-(4.4) are also illustrated in figure 1, where we observe a very good agreement with the exact, numerical results. It can be readily seen from (4.4), that eddies with high wavenumber $k$ potentially lead to structural instability and emergence of a mean flow with low wavenumber $n$, as then $s_n^{ad} > s_n^{vg}$. On the other hand, eddies with small $k$ are unable to lead to jet formation. Therefore, there is a minimum value $k_c$ for the eddies, below which all the eigenvalues $s_n$ are negative and the Reynolds stress divergence relaxes all mean flow perturbations back to the equilibrium state. This minimum wavenumber is a function of the forcing correlation scale $\delta$ and behaves as (c.f Appendix C):

$$k_c \sim 1/\sqrt{\delta},$$

for $\delta \ll 1$. As a result, for uncorrelated forcing for which $\delta \to 0$, the system is globally stable and no mean flows emerge. In the opposite limit of spatially correlated forcing ($\delta \to \infty$) the minimum wavenumber $k_c$ becomes 1.

From the limiting behavior of the eigenvalues for small $n$, we also see that advection of the eddy vorticity by the perturbed mean flow acts exactly as the anti-diffusion operator $-\tilde{\mu} d^2/dy^2$, with $\tilde{\mu}$ a positive constant. For a forcing that excites eddies with smaller
streamwise than spanwise scales \((k\delta \gg 1)\), \(c_2 l_e^2 \approx 2/k^2\) and the diffusion coefficient \(\tilde{\mu}(\epsilon, r, k, \delta)\) approaches a value that is independent of the spatial properties of the forcing \(\tilde{\mu} \approx \epsilon/2r\).

On the other hand, advection of the perturbed mean vorticity gradient by the eddies acts as a hyper-diffusion operator for large streamwise wavenumbers, \(k\), and as a diffusion operator for low \(k\) with the same diffusion coefficient \(\tilde{\mu}\) in the limit of \(k\delta \gg 1\).

Contours of the numerically calculated eigenvalues of \(S\) are plotted in figure 2 as a function of the mean flow wavenumber \(n\) and the streamwise wavenumber of the eddy field \(k\). As the streamwise wavenumber of the eddies increases, there is a larger number of eigenstructures for which the equilibrium state is potentially structurally unstable (that is \(s_n > 0\)), and the maximum eigenvalues occur at larger values of \(n\). The mean flow wavenumber \(n\) that produces the largest Reynolds stress sensitivity (jet forming stress) is readily shown from (4.4) in the limit of \(k\delta \gg 1\) to be at:

\[ n_{\text{max}} = k/\sqrt{2}, \]

yielding a maximum eigenvalue \(s_n = \epsilon k^2/8r\). The maximum mean flow wavenumber given by (4.5) is also shown in figure 2, where we can see a good agreement with the exact numerical results.

5. Instability characteristics

From (3.5), we can see that the structural stability of the state with no mean flow depends on the eddy dissipation \(r\) and the sensitivity of the Reynolds stress divergence as
Figure 2. Contours of the numerically calculated eigenvalues $s_n$ of the Reynolds stress sensitivity operator $\mathbf{S}$, as a function of the mean flow wavenumber $n$ and the streamwise wavenumber $k$ of the eddy field. The eigenvalues are divided by $k^2$ for each wavenumber for illustration purposes. The contour interval is 0.05, positive and negative values are shown by the solid and dashed lines respectively and the zero contour is shown by the thick solid line. Note that the contours are slightly jagged due to the fact that the values of $n$ are discrete. The mean flow wavenumber $n_{\text{max}}$ that corresponds to the largest eigenvalue and is given by (4.5), is also shown (thick dash dotted line) for reference. The values of $\epsilon$, $r$ influence only the values and not the form of the contours (here $\epsilon/r = 4$). The value of $\delta$ will influence the position of the zero contour line as discussed in the text (here $\delta = 0.25$).

measured by $s_n$. Two necessary conditions are required for instability to occur. The first condition is that $s_n$ should be positive for a mean flow perturbation with wavenumber $n$. That is, instability occurs only when the Reynolds stress divergence tends to reenforce the mean flow perturbation. As discussed in § 4, this condition is met when the streamwise wavenumber $k$ is above the minimum wavenumber $k_c$. The second condition is that the forcing variance $\epsilon$ should be above a certain threshold, so that the eddy forcing can overcome the mean flow dissipation. By solving (3.5) for the neutral stability condition $\lambda_n = 0$ and using (4.2), we obtain that for a mean flow perturbation with a given wavenumber $n$, this threshold is:

$$\epsilon_c = \frac{8r^3}{k^2(s^{ad}_n - s^{vg}_n)}.$$  \hfill (5.1)

The minimum input variance $\epsilon_{\text{min}} = \min_n(\epsilon_c)$ that is required to give rise to a mean flow with any wavenumber $n$ is given as the threshold for the wavenumber $n$ for which we have the maximum stress sensitivity (maximum $s^{ad}_n - s^{vg}_n$). Figure 3 illustrates the minimum input variance as a function of $k$. We observe that the minimum forcing amplitude drops rapidly with $k$, showing that forcing at larger streamwise wavenumbers is more efficient, as less eddy variance is needed to give rise to mean flows.

When the two necessary conditions are met, that is when $k > k_c$ and $\epsilon > \epsilon_{\text{min}}$, there is a number of emerging jets, whose mean velocity along with the corresponding Reynolds
stress divergence grow exponentially. The numerically calculated eigenvalues $\lambda_n$ for a given forcing strength are shown in figure 4a as a function of $n$ for two streamwise wavenumbers. As $k$ increases, there is a larger number of unstable jet structures and the maximum growth rate is attained at larger mean flow wavenumbers. Figure 4b shows the most unstable mean flow perturbation, when $k = 10$ along with the corresponding Reynolds stress divergence. We observe that the stress divergence is in phase with the mean flow perturbation and reinforces it. Therefore, both grow exponentially without any translation in $y$. The maximum growth rate as a function of $k$ is shown in figure 4c for a given eddy dissipation. The maximum growth rate is proportional to the streamwise wavenumber $k$ and also grows roughly as the square root of the forcing strength for large values of $\epsilon$ (not shown). The linear dependence on $k$ can be traced to the fact that the maximum stress sensitivity is $s_n = (\epsilon k^2/8r)$ (c.f § 4) leading to a $k^2$ factor within the square root in (3.5) that dominates the growth rate for large wavenumbers. We also observe that the growth rate increases with the correlation scale $\delta$, as the instability appears at lower streamwise wavenumbers. However, the slope of the maximum growth rate with $k$ is insensitive to the choice of $\delta$. The mean flow wavenumber $n$ of the jet that corresponds to the most unstable eigenvalue is plotted in figure 4d as a function of $k$. We observe that the width of the most unstable structure is proportional to the horizontal wavelength of the forcing as the mean flow wavenumber for which the maximum fluxes are attained is proportional to $k$ (cf (4.5)).

6. Sensitivity tests

In the previous sections we studied the structural stability of the flow with zero mean velocity and the underlying mechanisms, when the damping was linear and the forcing
Structural stability theory of two dimensional fluid flow under stochastic forcing

Figure 4. (a) Real part of the numerically calculated eigenvalues $\lambda_n$ of the structural stability operator $L$ as a function of mean flow wavenumber $n$ for $k = 10$ (dots) and $k = 15$ (circles). (b) The most unstable mean flow perturbation (solid line) and the corresponding Reynolds stress divergence (dashed line) for $k = 10$. (c) Maximum growth rate as a function of streamwise wavenumber $k$ for $\delta = 0.25$ (solid line) and $\delta = 0.1$ (dashed line). (d) Mean flow wavenumber $n$ for the most unstable eigenfunction (dots), as a function of $k$. A line of slope $2/3$ is also plotted for reference (solid line). For all panels $r = 0.2$, $\delta = 0.25$ and the input variance is $\epsilon = 0.01$.

6.1. Influence of diffusive dissipation

We first discuss the sensitivity of the obtained results to a change in the type of dissipation. The SSST system in the presence of diffusive dissipation is formulated in Appendix D. The structural stability of the zero mean flow is shown to be governed in the limit of small diffusion ($\nu \ll 1$) by the Reynolds stress sensitivity operator $S^v$ that is given by the expression:

$$
S^v = \frac{\epsilon k^2}{4} \begin{bmatrix} [I \circ (Q \Delta^{-2}) - \Delta^{-1} \circ (\Delta^{-1} Q)] - [I \circ (\Delta^{-2} Q \Delta^{-1}) - \Delta^{-1} \circ (\Delta^{-1} \Delta^{-1} Q)] D^2 \end{bmatrix}. \tag{6.1}
$$

Again, the two terms $S^{adv}$ and $S^{vgv}$ determine the sensitivity of the Reynolds stress divergence to changes in the mean velocity advection and to changes in the mean vorticity gradient respectively. Both are real symmetric circulant matrices with positive eigenvalues and the eigenvalues of $S^v$ are consequently given by: $s^v_n = (\epsilon k^2/4)(s^{adv}_n - s^{vgv}_n)$. The eigenvalues $s^{adv}_n$ and $s^{vgv}_n$ were numerically calculated for $N = 401$ grid points and are illustrated in figure 5 as a function of mean flow wavenumber $n$. Comparison to figure 1 shows the same qualitative behavior of the eigenvalues as determined by (4.3)-(4.4). The eigenvalues appear to be closely approximated by $s^{adv}_n \approx s^{ad}/k^2$ and $s^{vgv}_n \approx s^{vg}/k^2$ in the limits of validity of (4.3)-(4.4). The reason is that the equilibrium eddy...
covariance is proportional to $\Delta^{-1}Q$ instead of $Q$, adding roughly an additional $1/k^2$ factor to the eigenvalues. As a result, the eddy-mean flow feedbacks underlying the structural instability of the statistical equilibrium with no mean flow does not depend qualitatively on the details of the type of dissipation.

The eigenvalues of the structural stability operator $L$ are calculated in Appendix D. For low values of diffusion $\nu$, an approximate expression for $\lambda_n$ in terms of $s_{wv}^n$ was also derived (see equations (D 5) and (D 6)). Comparison of numerically calculated eigenvalues and those derived from (D 5) and (D 6) showed a very good agreement for $\nu = 10^{-3}$. Figure 6a shows the calculated eigenvalues $\lambda_n$ as a function of $n$ for this value of diffusion coefficient. Again the two necessary conditions for instability, that is $k > k_c$ and $\epsilon > \epsilon_{\text{min}}$ hold in this case as well. The critical minimum input variance $\epsilon_{\text{min}}$ required for structural instability is approximately

$$
\epsilon_{\text{min}} \sim \frac{\nu^3}{k^2} + O(\nu^4),
$$

for large streamwise wavenumbers. The growth rate of the structural instability is plotted in figure 6b. Since diffusive dissipation increases quadratically with wavenumber, the maximum growth rate is bounded for large $k$, unlike the case of linear damping. Finally, the width of the emerging jet is in this case as well proportional to the horizontal wavelength of the forcing, as the wavenumber $n_{\text{max}}$ of the jet corresponding to the most unstable eigenvalue is proportional to the streamwise wavenumber $k$ (not shown).

6.2. Influence of the forcing characteristics

We are interested in exploring qualitative changes of the obtained results in response to sources of eddy excitation other than vorticity forcing. We therefore take the forcing
covariance to be either $Q_v = \Delta^{-1} Q \Delta^{-1}$, or $Q_e = M^{-1/2} Q M$, where $M$ is the energy metric given by (C 8) and $Q$ is the forcing covariance matrix with the characteristics defined in § 2. The first choice, $Q_v$, corresponds to a stochastic excitation of cross-stream velocity with the same spatial and temporal correlation as in the vorticity forcing case. With the second choice, $Q_e$, we excite the system so that there is a Gaussian correlation in energy, rather than in vorticity. Therefore, an uncorrelated forcing would correspond in this case to each degree of freedom receiving equal energy.

The eigenvalues of the stress sensitivity operator $S$, as well as $S^{ad}$ and $S^{vg}$ were numerically calculated for each of the two cases. Figure 7 shows the eigenvalues $s^{ad}_n$ (figure 7a, 7c) and $s^{vg}_n$ (figure 7b, 7d) as a function of mean flow wavenumber $n$ for the case of $Q_v$. Similar results are obtained for $Q_e$ and are not shown. Comparison of figures 7 and 1, shows that for large streamwise wavenumbers, the results of § 3 are insensitive to the choice of forcing covariance. However, for smaller values of $k$, advection of the eddy vorticity produces a Reynolds stress divergence that is stabilizing and advection of the perturbed mean vorticity gradient by the eddies produces a Reynolds stress divergence that is destabilizing. As a result, we expect that the minimum wavenumber $k_c$, below which $s_n < 0$, will be larger in this case. This minimum wavenumber was empirically found to be $k_c \sim 1/\delta$ for $Q_v$, with a slightly different dependence for $Q_e$. Consequently, for a given correlation scale $\delta$, forcing with smaller cross-stream scales is required to form a streamwise jet. In addition, no jets emerge when the forcing is uncorrelated, regardless of the details of the forcing.

7. Discussion

We now summarize the main results of this work and compare them to other observational and modeling studies. In this study the initial structural instability of a zero mean flow under homogeneous forcing that leads to the emergence of streamwise jets was addressed. The basic assumption was that the interaction of the eddies with the mean flow is non-local in wavenumber space and that the eddy excitation can be modeled by a random process. First of all, we showed that advection of the eddy vorticity by the infinitesimal mean flow, that is shearing of the eddies, is the jet forming mechanism. This result is in agreement with previous numerical studies (Nozawa & Yoden 1997; Huang & Robinson 1998; Salyk et al. 2006; Kitamura & Ishioka 2007), who found that shearing of the eddies intensifies or sustains the mean flow. We also showed that the jets emerge when the forcing excites scales smaller than a certain minimum scale and when the forcing amplitude is above a certain threshold. When these two conditions are met, the eddy-mean
flow system is structurally unstable. Investigation of the structural instability revealed that the wavenumber of the most unstable mean flow perturbation is of the same order as the streamwise wavenumber $k$ of the most energetic eddies and the growth rate increases linearly with this $k$. This in agreement with Kitamura & Ishioka (2007), who found that forcing at small scales is necessary for jet formation as the eddies having small scales have the most significant contribution to momentum flux convergence.

However, it should be noted that neither the appearance of the initial instability guarantees the existence of a steady finite amplitude jet, nor the scale of the emerging infinitesimal mean flow necessarily coincides with the scale of the finite amplitude jet if this exists. Addressing this problem requires the study of the equilibration of the structural instability. Previous studies following the SSST approach (Farrell & Ioannou 2003, 2007, 2008, 2009), have shown that a finite amplitude jet may not be steady, as the non-linear eddy-mean flow system has also periodic solutions or a chaotic attractor. It was also shown in these studies that in addition to structural stability, perturbation stability also plays a crucial role in the evolution of the eddy-mean flow system. Therefore rotation (the $\beta$ effect), as well as the amount of eddy dissipation are key factors for the existence of steady solutions and the scale of the equilibrated jet, if such a solution exists. It was found that only in the case of marginal initial structural instability, the scale of the equilibrated jet coincides with the scale of the most unstable mean flow perturbation. In the case of stronger eddy forcing for which a stable equilibrium could be found, the most unstable perturbation predicted by this theory emerges initially. However the resulting finite amplitude jet that corresponds to this scale is perturbation unstable and the jet readjusts, forming a perturbation stable jet with a smaller mean flow wavenumber.

As a result, we typically under-predict the observed jet scale based only on the initial structural instability.
To illustrate this, we attempt to predict the spacing of the banded jets in Jupiter, using the results in this work. We nondimensionalize the equations, choosing \( L = 4000 \) km and \( T = 10 \) h (the length of the Jovian day) as the length and time scales respectively and \( V = L/T = 111 \) ms\(^{-1}\) as the velocity time scale. The channel then corresponds to a typical midlatitude portion of the Jovian atmosphere. We assume that the fluid is forced by convection. We therefore choose the de-correlation scale \( \delta \) to be the scale of the convective storms, which is \( 1000 \) km (Ingersoll et al. 2000), corresponding to a non-dimensional \( \delta = 0.25 \). The amplitude of the forcing, as well as the damping parameters for Jupiter are not well known individually. What is known is the turbulent large-scale rms velocity, which is \( O(5\text{ms}^{-1}) \) (Salyk et al. 2006). We therefore adjust \( \epsilon \) and \( r \) to produce the observed level of turbulence. We also assume that the eddy field comprises of a band of wavenumbers \( k \) with the largest wavenumber (non-dimensional \( k = 400 \)) corresponding to the horizontal scale of convection. The eigenvalues of the structural stability operator are given in this case by \( (3.9) \). The eigenfunction with the largest growth rate was found in this case to have a non-dimensional mean flow wavenumber \( n = 8 \) corresponding to a scale of \( 3000 \) km. This is about a third of the observed jet spacing in the Jovian atmosphere, but as discussed above we expect that the adjustments occurring during its equilibration will increase its scale towards the observed one as shown in Farrell & Ioannou (2007).

A different approach from SSST that also assumes non-local interactions in wavenumber space is modulational instability (Lorenz 1974; Gill 1974; Connaughton et al. 2010), in which the jets appear as a result of modulational rather than structural instability. The width of the emergent jet, is the scale with the fastest growth of a purely streamwise (zonal) wave interacting non-linearly with three Rossby waves, one of which is assumed to be a purely cross-stream (meridional) wave. The wavenumber of the fastest growing zonal wave (that is the mean flow wavenumber), is proportional to the streamwise wavenumber of the primary meridional wave and the fastest growth rate increases with the streamwise wavenumber (Connaughton et al. 2010). Both of these results are in agreement with the findings in this work. However, there is a significant difference with the SSST framework. In modulational instability the jet formation mechanism requires two main components: the first component is a finite amplitude cross-stream Rossby wave that is taken a-priori as the initial perturbation and is assumed to be excited by perturbation instability (for example baroclinic instability) of the large scale flow. The second component is the non-linear eddy-eddy interactions that actively participate in the jet forming process through the four wave interactions. As a result only a single wave is assumed to support the mean flow with the non-linear interactions acting as a catalyst for the energy transfer. In contrast, SSST does not require the existence of such finite amplitude waves and the mean flow is supported by its interaction with a very broad spectrum of waves rather than with a single wave. In addition, the eddy-eddy interactions do not participate in the energy transfer process. Nevertheless, it is worth noting that a special case of the structural instability that would resemble the modulational instability settings (although this would not be a one to one correspondence), would be to take the limit of a spatially correlated forcing \( (\delta \rightarrow \infty) \). In this limit, the mean flow is supported by a single cross-stream wave that is stochastically excited without however the catalytic action of the eddy-eddy interactions. The main results in this work were found to be insensitive to such a choice, as the growth rate does not depend qualitatively on the choice of \( \delta \) (c.f figure 4c).
8. Conclusions

Large-scale mean jets that are maintained by the very eddies they support, are commonly observed in turbulent fluids. Stability analysis of the coupled eddy-mean flow system is examined in this work within the framework of Stochastic Structural Stability Theory (SSST). In the context of SSST, the average eddy field and the average flow form a coupled dynamical system. The distribution of the eddy momentum fluxes associated with the structure of the large scale flow is obtained using a linear Stochastic Turbulence Model (STM) and the resulting Reynolds stress divergence forces the mean momentum equation.

Using SSST, the structural stability of a flow with no mean velocity, subjected to a homogeneous stochastic excitation is examined. The eigenvalues of the linear operator governing the evolution of mean flow perturbations and the associated eddy statistics were calculated for the zero mean flow equilibrium state. The structural stability was found to depend on the sensitivity of the Reynolds stress divergence to changes in the mean flow as quantified by the eigenvalues of the corresponding operator in the quasi-static limit. Calculation of the eigenvalues of this sensitivity operator, revealed two opposing physical mechanisms underlying the structural instability. The first is advection of the eddy vorticity by the infinitesimal jet perturbation, producing a Reynolds stress divergence that is destabilizing. In the physically relevant regime in which the mean flow perturbations have a large scale compared to the eddy scale, eddy vorticity advection was found to act exactly as a diffusion operator with a negative diffusion coefficient. Therefore the driving mechanism for the emergence of jets is shearing of the eddies by the mean flow. Opposing this tendency, is advection of the vorticity gradient of the mean flow perturbation by the eddies, producing a Reynolds stress divergence that is stabilizing. Advection of the mean flow vorticity gradient was found to act as a hyper-diffusion or as a diffusion operator (depending on the streamwise scale of the eddy field) for mean flow perturbations of large width. When the forcing excites eddies with larger streamwise than cross-stream scales, the diffusion coefficient resulting from each of these two processes was found to be the same and to depend only on the ratio of the eddy excitation over the eddy dissipation. Similar results were obtained when we considered forcing in cross-stream velocity, or in generalized energy coordinates and when we used a second order diffusion instead of linear damping as eddy dissipation. As a result, the characteristics of the physical mechanisms underlying jet emergence are qualitatively independent of the details of the forcing and of the eddy dissipation.

Structural instability and jet formation was found to occur if two necessary conditions were met. The first condition is that the Reynolds stress divergence tends to reenforce the mean flow perturbation, that is if the Reynolds stress divergence produced by eddy vorticity advection dominates. This condition is met if the eddies have scales smaller that a certain minimum scale. Since this minimum scale was found to be a decreasing function of the forcing correlation scale, a finite forcing correlation is needed for destabilizing Reynolds stresses. The second condition is that the eddy excitation should be above a certain threshold, so that the Reynolds stress divergence can overcome the mean flow dissipation. Although the coupled system was found to be unstable for a range of streamwise and mean flow wavenumbers, the maximum growth rate occurs for a jet structure having a width proportional to the streamwise wavelength of the most energetic eddies. For linear eddy dissipation, the maximum growth rate was found to be proportional to the streamwise wavenumber of the eddies, whereas for diffusive eddy dissipation, the maximum growth rate is bounded due to the attenuation of smaller width jets.

Appendix A. Calculation of the structural stability and the Reynolds stress sensitivity operator in the absence of diffusion

The equations for the evolution of small perturbations $\delta \mathbf{U}$, $\delta \mathbf{C}$ around the equilibrium values of mean velocity $\mathbf{U}^E$ and enstrophy covariance $\mathbf{C}^E$ are:

$$
\frac{d\delta \mathbf{C}}{dt} = A^E \delta \mathbf{C} + \delta \mathbf{C} A^E \mathbf{\dagger} + \left( \frac{\partial A^E}{\partial \mathbf{U}} \delta \mathbf{U} \right) \mathbf{C}^E + \mathbf{C}^E \left( \frac{\partial A^E}{\partial \mathbf{U}} \delta \mathbf{U} \right) \mathbf{\dagger},
$$

(A 1)

$$
\frac{d\delta \mathbf{U}}{dt} = \frac{\partial \mathbf{R}}{\partial \mathbf{C}} \delta \mathbf{C} - r \delta \mathbf{U}.
$$

(A 2)

For the equilibrium with no mean flow, $\mathbf{U}^E = 0$, the corresponding enstrophy covariance is given by (3.1) and

$$
A^E = -r I.
$$

(A 3)

Changes in the mean flow alter both the advection of eddy vorticity and the mean vorticity gradient that is advected by the eddies, resulting in a total change of the dynamics that is given by:

$$
\frac{\partial A^E}{\partial \mathbf{U}} \delta \mathbf{U} = -i k \text{diag}(\delta \mathbf{U}) + i k \text{diag}(D^2 \delta \mathbf{U}) \Delta^{-1}.
$$

(A 4)

By substituting (3.1), (A 3) and (A 4) into (A 1)-(A 2), and considering separate equations for the real, $\delta \mathbf{C}^R$, and imaginary, $\delta \mathbf{C}^I$, parts of the enstrophy covariance perturbation, we obtain:

$$
\frac{d\delta \mathbf{C}^R}{dt} = -2r \delta \mathbf{C}^R,
$$

(A 5)

$$
\frac{d\delta \mathbf{C}^I}{dt} = -2r \delta \mathbf{C}^I - k \frac{c}{2r} \left[ \text{diag}(\delta \mathbf{U}) Q - Q \text{diag}(\delta \mathbf{U}) \right] +
\frac{k c}{2r} \left\{ \text{diag} \left( D^2 \delta \mathbf{U} \right) \Delta^{-1} Q - Q \left[ \text{diag} \left( D^2 \delta \mathbf{U} \right) \Delta^{-1} \right] \right\},
$$

(A 6)

$$
\frac{d\delta \mathbf{U}}{dt} = -\frac{k}{2} \text{vecd} \left( \Delta^{-1} \delta \mathbf{C}^I \right) - r \delta \mathbf{U}.
$$

(A 7)

We first apply the vec operator to (A 6) and use the identity (B 7), as well as the fact that $\Delta^{-1}$ is Hermitian to obtain:

$$
\frac{d}{dt} \text{vec} \left( \delta \mathbf{C}^I \right) = -2r \text{vec} \left( \delta \mathbf{C}^I \right) + L^{IU} \delta \mathbf{U},
$$

(A 8)

where

$$
L^{IU} = -\frac{ek}{2r} \left\{ \mathbf{Q} \ast I - I \ast \mathbf{Q} - [(\mathbf{Q} \Delta^{-1}) \ast I \ast (\mathbf{Q} \Delta^{-1})] D^2 \right\}.
$$

We then use the identity vecd$(\Delta^{-1} \delta \mathbf{C}^I) = J \text{vec} (\Delta^{-1} \delta \mathbf{C}^I)$ proven in (B 10) as well as (B 2), to rewrite (A 7) as:

$$
\frac{d}{dt} \delta \mathbf{U} = L^{IU} \text{vec} \left( \delta \mathbf{C}^I \right) - r \delta \mathbf{U},
$$

(A 9)
where

\[ L_{UI} = -\frac{k^2}{4r^2} \left( I \otimes \Delta^{-1} \right). \]

As shown above, the \( N \times N^2 \) matrix \( J \) extracts the diagonal elements of a matrix that has been turned into a vector through the vec operator (cf. (B 10)). It is the matrix with non-zeros elements \( J_{i(i-1)(N+1)} = 1 \), that also satisfies \( JJ^T = I \). By construction, it has \( N \) linearly independent columns and as a result \( \text{rank}(J) = N \). The \( N \times N^2 \) matrix \( L_{UI} \) given by (3.3) is also of rank \( N \) and has a null space of dimension \( N^2 - N \). If we rewrite (A 5), (A 8), (A 9) in the notation of (2.8), we obtain the expression of the structural stability operator given by (3.2).

The sensitivity operator \( S = L_{UI}L_{IU} \) can be written in the form:

\[ S = \frac{\epsilon k^2}{4r^2} J \{ Q * I - I * Q - [ (Q\Delta^{-1}) * I - I * (Q\Delta^{-1}) ] D^2 \}, \]

or alternatively using (B 8):

\[ S = \frac{\epsilon k^2}{4r^2} J \{ Q * \Delta^{-1} - I * (\Delta^{-1} Q) - [ (Q\Delta^{-1}) * \Delta^{-1} - I * (\Delta^{-1} Q\Delta^{-1}) ] D^2 \}. \]

Finally applying (B 5) we obtain:

\[ S = \frac{\epsilon k^2}{4r^2} \left\{ [ Q \circ \Delta^{-1} - I \circ (\Delta^{-1} Q) - [ \Delta^{-1} \circ (Q\Delta^{-1}) - I \circ (\Delta^{-1} Q\Delta^{-1}) ] D^2 \right\}, \]

which is expression (4.1).

Appendix B. Identities involving the vec, vecd operators and the Khatri-Rao, Hadamard and Kronecker products

The Kronecker product of the \( k \times l \) matrix \( A \) with the \( m \times n \) matrix \( B \) is the \( km \times ln \) matrix \( A \otimes B \) defined as

\[ A \otimes B = \begin{pmatrix} A_{11}B & \cdots & A_{1l}B \\ \vdots & \ddots & \vdots \\ A_{k1}B & \cdots & A_{kl}B \end{pmatrix}. \] (B 1)

The Khatri-Rao product of two matrices \( A \) and \( B \) with columns \( a_i \) and \( b_i \) respectively is defined as

\[ A \ast B = [ a_1 \otimes b_1, a_2 \otimes b_2, \ldots, a_n \otimes b_n ] . \]

Throughout the text, the following identities concerning the vec, vecd operators and the Khatri-Rao, Hadamard and Kronecker products are used (Brewer 1978; Graham 1981):

\[ \text{vec}(AXB) = (B^T \otimes A)\text{vec}(X), \] (B 2)
\[ \text{vec}(I \circ A) = \text{diag}(\text{vec}(I)) \text{vec}(A), \] (B 3)
\[ \text{vecd}(A) = (I \circ A) e, \] (B 4)
\[ J(A \ast B) = A \circ B, \] (B 5)
\[ (e \otimes I) \text{diag}(\text{vec}(I)) = J, \] (B 6)
\[ \text{vec}(AYB) = (B^T \ast A) \text{vecd}(Y), \] (B 7)
\[ (A \otimes B)(C * D) = (AC) * (BD), \] (B 8)
where $A, B, C, D, X$ are matrices. $Y$ is a diagonal matrix, $I$ is the identity matrix, $e^T = [1 \ 1 \ ... \ 1]$ and $J$ is the $N \times N^2$ selection matrix given in Appendix A. $T$ denotes the transpose of a matrix, $\circ$ denotes the Hadamard-Schur entrywise product and $\ast$ denotes the Khatri-Rao product. Using (B2)-(B7) it can be readily shown that the following identities hold as well:

\[
\text{vec}([\text{diag}(a), B]) = (B^T \ast I - I \ast B) a,
\]

\[
\text{vecd}(A) = \text{vec}[\text{vecd}(A)] = \text{vec}[(I \circ A) e] = (e \otimes I)\text{vec}(I \circ A) = (e \otimes I)\text{diag}(\text{vec}(I))\text{vec}(A) = J\text{vec}(A),
\]

where $a$ is a vector.

### Appendix C. Analytic calculation of the eigenvalues of the flux sensitivity operator

An $N \times N$ matrix $C$ is circulant when its entries satisfy $C_{i,j} = C_{1,j-i \mod N}$. That is, each row is a cyclic shift of the row above it. An elaborate discussion of circulant matrices can be found in Davis (1978). Consider now the $N \times N$ circulant matrix $H$, where $N$ is taken without loss of generality to be an odd number. The first line of $H$ can be written as:

\[ h = [h_0 \ h_1 \ \cdots \ h_{(N-1)/2} \ h_{-(N-1)/2} \ h_{-(N-1)/2+1} \ \cdots \ h_{-2} \ h_{-1}], \]

and for real symmetric $H$ satisfies $h_{-n} = h_n$. The $m$-th eigenvalue ($1 \leq m \leq N$) is the Discrete Fourier Transform (DFT) of the elements of the matrix:

\[
\lambda_m^H = \sum_{n = -(N-1)/2}^{(N-1)/2} h_n e^{-2i\pi nm/N}, \tag{C1}
\]

It is real and satisfies the relation:

\[
\lambda_m^H = \left( \sum_{n = -(N-1)/2}^{(N-1)/2} h_n e^{-2i\pi nm/N} \right)^* = (\lambda_m^H)^* = \lambda_m^H.
\]

Therefore there are $(N - 1)/2$ double eigenvalues and one single. In addition, if the eigenvalues of a circulant matrix are known, then the elements of the matrix are the inverse DFT of the eigenvalues:

\[ h_m = \frac{1}{N} \sum_{n = -(N-1)/2}^{(N-1)/2} \lambda_m^H e^{2i\pi nm/N}. \]

The eigenvalues of the Hadamard product of two circulant matrices is given by the convolution of the eigenvalues of the two matrices:

\[
\lambda_n^{HC} = \sum_{m = -N/2}^{N/2} h_m g_m e^{-2i\pi nm/N} = \frac{1}{N^2} \sum_{m = -N/2}^{N/2} \sum_{k = -N/2}^{N/2} \sum_{l = -N/2}^{N/2} \lambda_k^H e^{2i\pi mk/N} \lambda_l^G e^{2i\pi ml/N} e^{-2i\pi nm/N} = \frac{1}{N} \sum_{k = -N/2}^{N/2} \sum_{l = -N/2}^{N/2} \lambda_k^H \lambda_l^G \delta_{(k+l-n)0 \mod N} = \frac{1}{N} \sum_{k = -N/2}^{N/2} \sum_{l = -N/2}^{N/2} \lambda_k^H \lambda_l^G \delta_{n = k \mod N}. \tag{C2}
\]
For $n > 0$, (C2) can be rewritten as:

$$\lambda_n^{H,G} = \frac{1}{N} \sum_{m=-\frac{N-1}{2}}^{\frac{N-1}{2}} \lambda_m H \lambda_{m-N} + \frac{1}{N} \sum_{m=-\frac{N-1}{2}}^{\frac{N-1}{2}} \lambda_m H \lambda_{m-N},$$

(C3)

and for $n = 0$:

$$\lambda_0^{H,G} = \frac{1}{N} \sum_{m=-\frac{N-1}{2}}^{\frac{N-1}{2}} \lambda_n H \lambda_{n-N}.$$  

As a result, the eigenvalues $s_{n}^{ad}$ and $s_{n}^{vg}$ are given by:

$$s_{n}^{ad} = \lambda_n^{A^{-1}} \nu - \lambda_n^{Q} \left( \lambda_n^{Q} \mod N - \lambda_n^{Q} \right),$$

(C4)

$$s_{n}^{vg} = \lambda_n^{A^{-1}} \nu \left( \nu Q \right) - \lambda_n^{Q} \left( \lambda_n^{Q} \mod N - \lambda_n^{Q} \right),$$

(C5)

were

$$\lambda_n^{A^{-1}} = -\frac{1}{k^2 + n^2}, \quad \lambda_n^{Q} = -n^2,$$

(C6)

are the eigenvalues of $A^{-1}$, $D^2$ and $\lambda_n^{Q}$ are the eigenvalues of $Q$ to be calculated.

The eigenvalues of $Q$ are given by $\lambda_n^{Q} = (\lambda_n^{F})^2$, where $\lambda_n^{F}$ are the eigenvalues of the forcing matrix $F$. The first line of $F$ is:

$$f_m = A \left( e^{-m \delta y^2 / \delta^2} + e^{-2(m-\delta y)^2 / \delta^2} + e^{-2(m+\delta y)^2 / \delta^2} \right),$$

where $A$ is the forcing amplitude, $\delta$ is the forcing correlation scale and $\delta y$ is the discretization scale. The eigenvalues of $F$ are then given according to (C1) by:

$$\lambda_n^{F} = \frac{A}{\delta y} \sum_{m=-\frac{N}{2}}^{\frac{N-1}{2}} \left( e^{-y_m^2 / \delta^2} + e^{-2(y_m)^2 / \delta^2} + e^{-2(y_m+y)^2 / \delta^2} \right) e^{-i \delta y m \delta y},$$

where $y_m = m \delta y = 2m \delta y$. The major contribution to the sum comes from the terms near $m = 0$ for which $|f_0 - f_1|/|f_0| O(\delta y^2)$. Therefore in the continuous limit ($\delta y \to 0$), the sum can be approximated by the integral:

$$\lambda_n^{F} = \frac{A}{\delta y} \int_{-\pi}^{\pi} \left( e^{-y^2 / \delta^2} + e^{-2y^2 / \delta^2} + e^{-2(y+y)^2 / \delta^2} \right) e^{-i \delta y y} dy =$$

$$= \frac{A \delta \sqrt{\pi}}{2 \delta y} e^{-n^2 \delta^2 / 4} \left[ \text{erf} \left( \frac{3 \pi}{\delta} + \frac{i \delta \pi}{2} \right) + \text{erf} \left( \frac{3 \pi}{\delta} - \frac{i \delta \pi}{2} \right) \right],$$

that in the limit of $\delta \ll 1$ becomes

$$\lambda_n^{Q} = (A \delta \sqrt{\pi} / \delta y) e^{-n^2 \delta^2 / 4},$$

yielding:

$$\lambda_0^{Q} = \frac{A \delta \sqrt{\pi}}{\delta y^2} e^{-n^2 \delta^2 / 2}. \quad \text{(C7)}$$

The forcing amplitude is constrained to impart an input variance that is equal to the
Structural stability theory of two dimensional fluid flow under stochastic forcing

energy of a constant flow of unit velocity:

\[ \lim_{\delta y \to 0} \text{tr} (MQ) = \int_0^{2\pi} \frac{L^2}{2} dy = \pi, \]

where

\[ M = -\frac{\delta y}{4} \Delta^{-1}, \quad \text{(C 8)} \]

is the metric such that the eddy energy is given by the inner product \( E = q^\dagger M q \). From (C6), (C7) we obtain that the forcing normalization is:

\[ \frac{1}{A^2} = \frac{\delta^2}{4\delta y} \frac{(N-1)/2}{\sum_{m=-(N-1)/2}^{(N-1)/2} e^{-m^2\delta^2/2}}. \quad \text{(C 9)} \]

C.1. Proof that the eigenvalues of \( S^{ad} \) and \( S^{eg} \) are non-negative

We rewrite (C4) and (C5) using (C3):

\[ s_n^{ad} = \frac{1}{N} \sum_{m=-N/2}^{N/2-1} \lambda_m^{-1} \left( \lambda_n^{-1} - \lambda_m^0 \right) + \frac{1}{N} \sum_{m=-N/2}^{N/2-1} \lambda_m^{-1} \left( \lambda_n^0 - \lambda_m^0 \right), \quad \text{(C 10)} \]

\[ s_n^{eg} = -\frac{n^2}{N} \sum_{m=-N/2}^{N/2-1} \lambda_m^{-1} \left( \lambda_n^{-1} - \lambda_m^{-1} \right) - \frac{n^2}{N} \sum_{m=-N/2}^{N/2-1} \lambda_m^{-1} \left( \lambda_n^0 - \lambda_m^0 \right), \quad \text{(C 11)} \]

Assume without loss of generality that \( n \) is an even integer. By expanding the sums in (C10), (C11), reorganizing the terms and taking common factors, it can be shown that (C10) and (C11) can be rewritten as:

\[ s_n^{ad} = \frac{1}{N} \sum_{m=0}^{N/2-1} \left( \lambda_n^{-1} - \lambda_m^{-1} \right) \left( \lambda_n^0 - \lambda_m^0 \right), \quad \text{(C 12)} \]

\[ s_n^{eg} = -\frac{n^2}{N} \sum_{m=0}^{N/2-1} \left( \lambda_n^{-1} - \lambda_m^{-1} \right) \left( \lambda_n^0 - \lambda_m^0 \right) \quad \text{(C 13)} \]

Since \( \lambda_n^{-1} - \lambda_m^{-1} > \lambda_n^0 - \lambda_m^0 \) and \( \lambda_n^0 - \lambda_m^0 > \lambda_n^{-1} - \lambda_m^{-1} \) it follows from (C12), (C13) that \( s_n^{ad} > 0 \) and \( s_n^{eg} > 0 \).

C.2. Eigenvalues for jet structures with small mean flow wavenumber

Analytic calculation of the eigenvalues \( s_n^{ad}, s_n^{eg} \) for low \( n \) proceeds as follows. First of all, note that the constant mean flow eigenstructure is neutral as it can be readily shown that for \( n = 0 \), (C4) and (C5) yield: \( s_0^{ad} = s_0^{eg} = 0 \). Using (C3) and for eigenstructures with
small mean flow wavenumber satisfying \( k_c > n \delta y \) (that also satisfy \( (N - 1)/2 - n > 1 \)), (C4) and (C5) can be approximated by:

\[
s_n^{ad} \simeq \frac{1}{N} \sum_{m=-\infty}^{N-1} \lambda_m^{\Delta} \lambda_{n-m}^{Q} - \frac{1}{N} \sum_{m=-\infty}^{N-1} \lambda_m^{\Delta} \lambda_m^{Q} = \frac{1}{N} \sum_{m=-\infty}^{N-1} (p_1(n, m) - p_1(m, 0)),
\]

and

\[
s_n^{vg} \simeq \frac{\lambda_n^{Q^2}}{N} \sum_{m=-\infty}^{N-1} \lambda_m^{\Delta^{-1}} \left( \lambda_m^{Q^{-1}} - \lambda_m^{\Delta^{-1}} \right) = \frac{n^2}{N} \sum_{m=-\infty}^{N-1} \sum_{n} (p_2(n, m) - p_2(m, 0)),
\]

where

\[
p_1(n, m) = \lambda_m^{\Delta^{-1}} \lambda_{n-m}^{Q} = -A^2 \delta^2 \pi e^{-(n-m)^2 \delta^2/2} \delta y \frac{\delta^2}{k^2 + m^2},
\]

and \( p_2(m, n) = -\lambda_m^{\Delta^{-1}} \lambda_{n-m}^{Q^{-1}} = p_1(n, m)/[k^2 + (m - n)^2] \). For \( n << 2 \pi \) the major contribution to the sums comes from the terms close to \( m = 0 \) for which:

\[
S = \frac{|p_0(0, n) - p_1(1, n)|}{p_1(0, n)} \simeq \frac{1}{(k^2 + 1)^2}.
\]

In the limit of large streamwise wavenumber \( (k_l_c > 1), S \ll 1 \) and the sums in (C14) and (C15) can be approximated by integrals that in the continuous limit and after changing variables become:

\[
s_n^{ad} \simeq -\frac{A^2 \delta^2 \pi}{N \delta y} \int_{-\infty}^{\infty} \frac{e^{-(n-t)^2 \delta^2/2} - e^{-t^2 \delta^2/2}}{k^2 + t^2} dt,
\]

\[
s_n^{vg} \simeq \frac{A^2 \delta^2 \pi}{N \delta y} n^2 \int_{-\infty}^{\infty} \left( \frac{e^{-(n-t)^2 \delta^2/2}}{(k^2 + t^2)(k^2 + (n-t)^2)} - \frac{e^{-t^2 \delta^2/2}}{(k^2 + t^2)^2} \right) dt.
\]

Similarly (C9) is reduced to:

\[
\frac{1}{A^2} = \frac{\delta^2}{4 \delta y} \int_{-\infty}^{\infty} \frac{e^{-t^2 \delta^2/2}}{k^2 + t^2} dt = 1,
\]

yielding:

\[
A = \sqrt{\frac{4 \delta y \exp(-k^2 \delta^2/2)}{\delta^2 \pi \text{erfc}(k \delta/\sqrt{2})}}. \tag{C16}
\]

Expanding the integrands in powers of \( n \), we obtain after substitution of \( A \) from (C16) that \( s_n^{ad} \) and \( s_n^{vg} \) are given by (4.4), where:

\[
c_2(k, \delta) = \delta^2 \left( 1 + k^2 \delta^2 - \frac{\sqrt{2 \pi} \delta k e^{-k^2 \delta^2/2}}{\pi \text{erfc}(k \delta/\sqrt{2})} \right), \tag{C17}
\]

\[
c_3(k \delta) = \frac{1}{12} \left( 3 - 3k^4 \delta^4 - 2k^6 \delta^6 + \sqrt{2 \pi} \delta k (3 + k^2 \delta^2 + 2k^4 \delta^4) \frac{e^{-k^2 \delta^2/2}}{\pi \text{erfc}(k \delta/\sqrt{2})} \right). \tag{C18}
\]

For \( k \delta \gg 1 \) (C17) and (C18) can be further approximated to yield:

\[
c_2 = 2/k^2, \quad c_3 = 2
\]
Structural stability theory of two dimensional fluid flow under stochastic forcing

and for $k\delta \ll 1$ they become

$$c_2 = \delta^2 (1 - \sqrt{2/\pi} k\delta), \quad c_3 = (1/4)(1 + \sqrt{2/\pi} k\delta).$$

As a result, in the limit of correlated forcing ($\delta \to \infty$), $s_n \simeq (ek^2/4r)(2n^2/k^2 - 2n^4/k^4)$ is positive for the gravest mode ($n = 1$) only if $k > k_c = 1$. For $k\delta \ll 1$, $s_n \simeq (ek^2/4r)(\delta^2 n^2 - n^4/4k^4)$ and the corresponding cut-off wavenumber is $k_c = 1/\sqrt{2\delta}$. In the limit of low streamwise wavenumber ($kl_c \ll 1$), the sums in (C9), (C14) and (C15) are dominated by the $m = 0$ terms. Keeping only this term and in the limit of $n\delta y \ll l_c$, (C9), (C14) and (C15) become:

$$A = \sqrt{\frac{4k^2\delta y}{\pi}},$$

$$s_n^{ad} \simeq -\frac{A^2\delta^2\pi}{N\delta y^2} \left( \frac{e^{-n^2\delta^2/2}}{k^2} - \frac{1}{k^2} \right) \simeq \frac{A^2\delta^4\pi}{2N\delta y^2k^2} n^2 \simeq \delta^2 n^2, \quad (C 19)$$

and

$$s_n^{eg} \simeq -\frac{A^2\delta^2\pi}{N\delta y^2} n^2 \left( \frac{e^{-n^2\delta^2/2}}{k^2(k^2 + n^2)} - \frac{1}{k^2} \right) \simeq \frac{A^2\delta^2\pi}{N\delta y^2k^4} n^2 \simeq \frac{2}{k^2} n^2, \quad (C 20)$$

respectively.

C.3. Eigenvalues for jet structures with large mean flow wavenumber

We now calculate an analytic expression for the eigenvalues $s_n^{ad}, s_n^{eg}$ for eigenstructures with large mean flow wavenumber $n\delta y O(l_c/2)$, for which (C4) and (C5) can be approximated by:

$$s_n^{ad} \simeq \frac{2}{N} \sum_{m=-(N-1)/2+n}^{N-1} \lambda_m^{Q} \lambda_{n-m}^{\Delta^{-1}} - \frac{1}{N} \sum_{m=-(N-1)/2+n}^{N-1} \lambda_m^{\Delta^{-1}} \lambda_m^{Q}, \quad (C 21)$$

and

$$s_n^{eg} \simeq \frac{2\lambda_D^2}{N} \sum_{m=-(N-1)/2+n}^{N-1} \lambda_m^{\Delta^{-1}} \lambda_{n-m}^{\Delta^{-1}} - \frac{\lambda_D^2}{N} \sum_{m=-(N-1)/2+n}^{N-1} (\lambda_m^{\Delta^{-1}})^2 \lambda_m^{Q}. \quad (C 22)$$

The second term in (C 21) is equal to $-2$ due to (C9). It can also be readily shown that in the limit of large streamwise wavenumbers ($kl_c \gg 1$), the rest of the sums in (C21) and (C22) can be approximated by integrals that in the continuous limit and for $n\delta y O(l_c/2)$ become:

$$s_n^{ad} \simeq 2 - \frac{2A^2\delta^2\pi}{N\delta y^2} \int_0^\infty \frac{e^{-m^2\delta^2/2}}{k^2 + (n-m)^2} dm \simeq 2 - \frac{8A^2\delta^2\pi}{N^3\delta y^2} \int_0^\infty e^{-m^2\delta^2/2} dm, \quad (C 23)$$

$$s_n^{eg} \simeq \frac{2A^2\delta^2\pi}{N\delta y^2} \int_0^\infty \frac{e^{-m^2\delta^2/2}}{k^2 + m^2} \left( \frac{1}{k^2 + m^2} - \frac{1}{k^2 + (n-m)^2} \right) dm \simeq \frac{2A^2\delta^2\pi}{N\delta y^2} \int_0^\infty \frac{e^{-m^2\delta^2/2}}{k^2 + m^2} \left( \frac{1}{k^2 + m^2} - \frac{4}{N^2} \right) dm. \quad (C 24)$$

After calculation of the integrals and substitution of $A$ by (C16), equations (C23) and (C24) yield:

$$s_n^{ad} \simeq 2 - O(\delta y)^2,$$
\[
s_{ng}^v \simeq n^2 k^2 \left( 1 - k^2 \delta^2 + k\delta \sqrt{2\pi e^{-k^2 \delta^2/2}}/\text{erfc}(k\delta/\sqrt{2}) \right) + O(\delta y^2).
\]

(C 25)

On the other hand, in the limit of low streamwise wavenumbers \((kL_c \ll 1)\), the sums in (C 9), (C 21) and (C 22) are dominated by the \(n = 0\) terms. Keeping only this term, we obtain:

\[
\begin{align*}
    s_{ng}^v & \simeq n^2 k^2 \left( 1 - k^2 \delta^2 + k\delta \sqrt{2\pi e^{-k^2 \delta^2/2}}/\text{erfc}(k\delta/\sqrt{2}) \right) + O(\delta y^2) \\
    s_{ng}^a & \simeq 2 - O(\delta y^2).
\end{align*}
\]

Therefore \(s_{ng}^v\) is given by (4.3) with:

\[
c_1(k\delta) = \begin{cases} 
    2, & \text{for } kL_c \ll 1 \\
    1 - k^2 \delta^2 + k\delta \sqrt{2\pi e^{-k^2 \delta^2/2}}/\text{erfc}(k\delta/\sqrt{2}), & \text{for } kL_c \gg 1
\end{cases}
\]

(C 26)

**Appendix D. Calculation of the eigenvalues of the structural stability operator in the presence of diffusion**

When the effective eddy dissipation is only diffusive (that is \(r = 0\) and \(\nu \neq 0\)), it can be readily shown that for \(U^E = 0\):

\[
A^E = \nu \Delta,
\]

(D 1)

and the corresponding covariance at equilibrium is:

\[
C^E = -\epsilon \Delta^{-1} Q \frac{2}{2\nu}.
\]

(D 2)

Substituting (D 1), (D 2) and (A 4) into (A 1), (A 2) and applying the vec operator we obtain:

\[
L = \begin{pmatrix}
    \nu \Delta & 0 \\
    0 & \nu \Delta
\end{pmatrix}
\begin{pmatrix}
    \Delta & L^{Ud}/\nu \\
    L^{Ud}/\nu & \nu D^2
\end{pmatrix},
\]

(D 3)

where \(\oplus\) denotes the Kronecker sum and

\[
L^{Ud} = \frac{k\epsilon}{2} \left\{ (\Delta^{-1} Q) * I - I * (\Delta^{-1} Q) - [(\Delta^{-1} Q \Delta^{-1}) * I - I * (\Delta^{-1} Q \Delta^{-1})] D^2 \right\}.
\]

Similarly to the case of linear eddy dissipation, it can be shown from (D 3) that the stability operator \(L\) has \(2N^2 - N\) eigenvalues \(\nu^2[2k^2 + n^2 + m^2], \ n = 1, ..., N, \ m = 1, ..., N\) with corresponding eigenvectors having \(\delta U = 0\) that are therefore not of interest for the emergence of mean flows. The remaining \(2N\) eigenvalues are given by the solution to:

\[
\det \left\{ \lambda + \frac{1}{\nu} L^{Ud} [\lambda_{N^2} - \nu \Delta \oplus \Delta]^{-1} L^{Ud} - \nu D^2 \right\} = 0.
\]

(D 4)

Assuming that \(\nu \ll \lambda\), we can approximate \([\lambda_{N^2} - \nu \Delta \oplus \Delta]^{-1} \simeq \lambda^{-1} I + \nu \Delta \oplus \Delta/\lambda^2\). Then, (D 4) can be solved perturbatively by expanding the eigenvalues in powers of \(\nu\):

\[
\lambda_n^0 = \pm \sqrt{s_n^v}, \ n = 1, .., N,
\]

(D 5)

\[
\lambda_n^1 = \frac{\lambda_n^{Ud}}{2s_n^v} - \frac{n^2}{2}, \ n = 1, .., N.
\]

(D 6)
Structural stability theory of two dimensional fluid flow under stochastic forcing

$s^n_v$ are the eigenvalues of the $N \times N$ matrix $S^v = L^{UI} L^{IUd}$ and $\lambda^{U1\Delta}_n$ are the eigenvalues of $L^{U1\Delta} = L^{UI}(\Delta \oplus \Delta) L^{IUd}$. Therefore, the stability of the equilibrium resting state is determined to a first order by the eigenvalues $s^n_v$ of the corresponding sensitivity operator in the viscous case. Working in a similar way as in Appendix A, we use (B 5) and (B 8) to reduce the expression of the sensitivity operator to (6.1).
